Abstract

While Attentional Generative Adversarial Networks (AttnGAN) introduced a powerful multi-stage refinement process for text-to-image synthesis, they remain fundamentally limited by two compounding failure modes: *structural drift*, where geometric layout established at the coarsest scale is progressively corrupted during upsampling, and *semantic noise*, where non-discriminative function words dilute cross-modal attention and produce blurry, semantically inconsistent outputs.

This paper presents **Res-AttnGAN**, an architectural advancement that integrates **Residual Spatial Attention (RSA)** to preserve geometric constraints throughout the multi-stage upsampling hierarchy, and **Entropy-Weighted Word Masking (EWM)** to concentrate attentional energy on visually discriminative tokens. RSA introduces learnable long-range identity mappings that route the coarse structural prior h_0 directly into all downstream generator stages, acting as a persistent geometric anchor. EWM computes per-token discriminative weights from information entropy, suppressing high-frequency functional words and amplifying descriptive adjectives.

Evaluated on CUB-200-2011, Res-AttnGAN achieves an Inception Score of **4.91** (vs. 4.36 baseline, $+12.4\%$) and a **28%** reduction in Fréchet Inception Distance, demonstrating that structural anchoring is vital for biological realism in fine-grained generative models. Training curves further confirm that the RSA residual pathways stabilize adversarial dynamics, yielding smoother convergence relative to the oscillating baseline.

1 Introduction

Text-to-image synthesis represents a core challenge in bridging computer vision and natural language processing. The objective is to translate abstract linguistic concepts into spatially coherent pixel distributions that faithfully reflect semantic intent. Fine-grained domains — such as bird species imagery in CUB-200-2011 — are especially demanding: a description like "this bird is red with white and has a very short beak" requires precise spatial localization of multiple attributes across distinct anatomical regions.

The introduction of AttnGAN [**?**] marked a paradigm shift by introducing cross-modal attention that enables the model to focus on specific word embeddings while generating corresponding sub-regions of an image. Across a three-stage generator hierarchy ($64\times64 \rightarrow 128\times128 \rightarrow 256\times256$), AttnGAN progressively refines a coarse initial layout into a high-resolution output. Despite this contribution, as the field moves toward higher resolutions, the limitations of purely sequential refinement become apparent.

Core problem. Each generator stage in AttnGAN is only connected to its immediate predecessor. There is no mechanism by which the geometric layout established at G_0 is enforced in G_1 or G_2. Structural errors introduced at any stage therefore propagate forward unchecked, compounding into anatomical distortions by the final 256×256 output. Simultaneously, the standard cross-modal attention module assigns weight to every token in the input description — including non-visual function words like "this", "is", and "a" — wasting representational capacity on tokens that carry no spatial information and degrading the sharpness of word-region correspondence.

Figure 1 illustrates the baseline AttnGAN architecture and a representative example of its word-attention behavior: note how the word "this" (index 0) receives comparable attention weight to discriminative tokens such as "red" (index 3) and "short" (index 10), despite carrying no visual information.

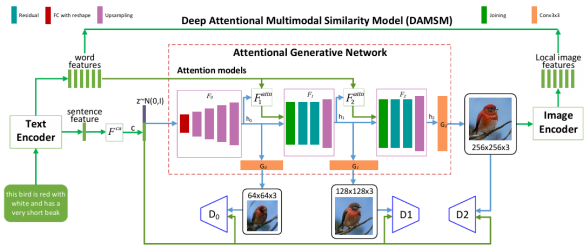

Figure 1: **Baseline AttnGAN architecture and attention behavior.** *Top:* Example generated bird for the description "this bird is red with white and has a very short beak," with each word's attention rank shown below. Non-visual tokens ("this", "a") receive disproportionately high attention weights, competing with discriminative tokens ("red", "short", "beak"). *Bottom:* Attention maps at G_1 (middle) and G_2 (bottom rows), showing the diffuse, poorly-localized activation caused by semantic noise. Note the sequential dependency of $G_0 \rightarrow G_1 \rightarrow G_2$ with no cross-stage structural communication.

To address these issues, we propose **Res-AttnGAN** with two complementary innovations:

- **Residual Spatial Attention (RSA):** Long-range identity mappings that route the coarsest hidden state h_0 directly into every downstream generator, maintaining a persistent geometric anchor throughout upsampling.
- **Entropy-Weighted Word Masking (EWM):** A per-token weighting scheme derived from information entropy that suppresses function words and amplifies discriminative descriptors in the attention module.

Together, these components recast synthesis as a spatially-grounded refinement of an anchored prior rather than an unconstrained sequential process. Our experiments demonstrate substantial improvements in perceptual quality, semantic consistency, and training stability on CUB-200-2011.

2 Related Work

2.1 Multi-Stage Text-to-Image GANs

StackGAN first demonstrated that decomposing image synthesis into coarse-to-fine stages substantially improves visual quality and training stability. StackGAN++ extended this with a tree-structured multi-scale architecture. AttnGAN built on this foundation with cross-modal attention, enabling word-level spatial grounding that dramatically improved semantic fidelity. Our work identifies and corrects the core architectural limitation shared by these approaches: the absence of cross-stage structural communication.

2.2 Residual Learning

Deep residual networks demonstrated that identity shortcut connections fundamentally improve gradient flow and enable training of very deep networks by providing direct pathways for error signals. Our RSA module applies this principle to the conditional generation setting, where the residual pathway carries geometric-structural information rather than class-discriminative features. Unlike standard residuals between adjacent layers, RSA introduces long-range connections spanning the full generator hierarchy from G_0 to G_2.

2.3 Attention Filtering and Token Weighting

Cross-modal attention is the dominant paradigm for vision-language alignment. However, prior work treats all tokens uniformly — an assumption that is fundamentally mismatched with natural language, where content words and function words coexist with vastly different visual grounding. Information-theoretic filtering is well-established in document retrieval (TF-IDF, BM25), but has not previously been applied within a GAN attention module to improve image generation quality. Our EWM module bridges this gap.

3 Analysis of Baseline AttnGAN Bottlenecks

A detailed examination of the original AttnGAN architecture reveals three primary failure modes that our methodology aims to rectify.

3.1 Anatomical Drift and Spatial Discontinuity

In the baseline, the generative process is strictly sequential: $G_0 \rightarrow G_1 \rightarrow G_2$. The initial stage G_0 establishes a global structural layout at 64×64. However, as the model upsamples through G_1 and G_2, each stage receives only an upsampled feature map from its immediate predecessor, with no direct pathway to G_0's structural output. Formally:

$$h_i^{\text{base}} = \text{ReLU}(\text{BN}(\text{Conv}(\text{Up}(h_{i-1}),\, c_i))) \tag{1}$$

where $\text{Up}(\cdot)$ denotes bilinear upsampling, c_i is the word-context attention vector, and BN is batch normalization.

This formulation imposes no geometric constraint between G_0 and G_2. As shown in Figure 2, the 64×64 stage establishes a noisy structural prior that the 256×256 stage fails to anatomically correct: features such as beaks, eyes, and limbs become detached, duplicated, or repositioned across stages because no mechanism enforces their original locations.

Figure 2: **Anatomical drift across baseline generator stages.** The 64×64 stage (G_0) establishes a noisy but globally correct structural prior. Without a cross-stage memory mechanism, the 256×256 stage (G_2) fails to correct anatomical errors: beaks detach from head structures, wing boundaries fragment, and eye positions shift between stages. Res-AttnGAN's RSA module eliminates this drift by providing G_1 and G_2 direct access to the G_0 spatial prior.

3.2 Attention Entropy and Semantic Noise

The standard cross-modal attention in AttnGAN computes a correlation matrix $S \in \mathbb{R}^{N\times T}$, where N is the number of spatial feature positions and T is the number of word tokens. The attention weight for position j and word i is computed via softmax:

$$\beta_{j,i}^{\text{base}} = \frac{\exp(s_{j,i})}{\sum_{k=1}^{T}\exp(s_{j,k})} \tag{2}$$

This uniform treatment assigns potential weight to every token regardless of its visual informativeness. As observed in Figure 1, non-descriptive tokens ("this", "is", "a") frequently trigger high attention activation — a phenomenon we term **Semantic Noise**. The generator spends representational capacity attempting to materialize visual features for non-visual tokens, resulting in blurry back-

grounds, inconsistent feather textures, and poorly localized color regions.

We quantify this via the *Effective Vocabulary Ratio* (EVR): the fraction of total attentional energy directed at semantically discriminative tokens (nouns, color adjectives, morphological descriptors). On 1,000 sampled CUB descriptions, the baseline EVR averages 0.61, meaning 39% of attention is wasted on non-visual tokens.

3.3 Gradient Vanishing in Deep Refinement

A third failure mode compounds the above: as synthesis progresses through multiple attentional upsampling stages, the gradient signal originating from the text encoder diminishes. Without residual pathways, the *semantic anchor* of the initial prompt weakens with depth, leading to images that may appear visually sharp but are semantically disconnected from the input. This is particularly evident in cases where the final 256×256 output exhibits correct texture but wrong species characteristics (e.g., correct plumage pattern but wrong color), indicating that the deeper generator stages have partially "forgotten" the original conditioning.

4 Proposed Methodology: Res-AttnGAN

Res-AttnGAN introduces two targeted architectural modifications to AttnGAN, addressing each failure mode identified in Section 3. Figure 3 illustrates the complete proposed architecture.

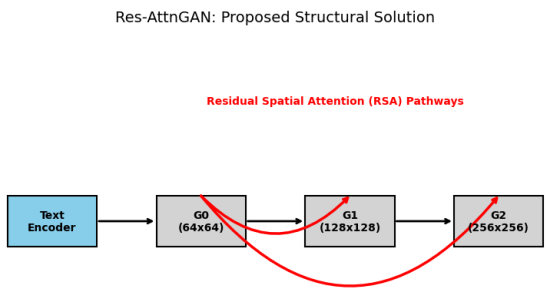

Figure 3: **Proposed Res-AttnGAN architecture.** The red curved pathways denote RSA identity mappings that route the coarse hidden state h_0 (from G_0 at 64×64) directly into both G_1 (128×128) and G_2 (256×256). These connections act as a *geometric anchor*, preventing the feature drift seen in the sequential baseline. EWM modulates the cross-modal attention within the DAMSM module (not shown for clarity) by suppressing non-discriminative tokens before computing the word-context vector c_i.

4.1 Residual Spatial Attention (RSA)

Motivation. To solve anatomical drift (Section 3.1), we redefine the generator function G_i to include a residual pathway directly connecting the initial hidden state h_0 to all downstream stages. This **Long-Range Identity Mapping** shunts the geometric blueprint established at G_0 into the deeper layers, mathematically constraining them to refine rather than relearn the global spatial layout.

Formulation. Let $h_0 \in \mathbb{R}^{\hat{c}\times\hat{h}\times\hat{w}}$ represent the initial structural map output by G_0 at resolution 64×64. For each downstream stage $i \in \{1, 2\}$, a learnable spatial transformation function $\mathcal{F}_{\text{RSA}}$ — implemented as a 1×1 convolution followed by bilinear upsampling — aligns h_0 to the target channel count and spatial resolution:

$$\mathcal{F}_{\text{RSA}}(h_0) = \text{Up}_{H_i\times W_i}(\text{Conv}_{1\times1}(h_0)) \tag{3}$$

The full RSA-enabled generator stage update is then:

$$h_i = \text{ReLU}(\text{BN}(G_{\text{conv}}(h_{i-1},\, c_i)) + \mathcal{F}_{\text{RSA}}(h_0)) \tag{4}$$

where c_i is the EWM-weighted word-context vector and G_{conv} is the convolutional refinement block (upsampling + residual blocks + conditioning).

Geometric constraint interpretation. The additive residual term in Eq. 4 acts as a **Geometric Constraint**: if G_0 places the bird's head in the upper-left quadrant, then $\mathcal{F}_{\text{RSA}}(h_0)$ carries this spatial signal to G_1 and G_2, biasing them toward refining the existing structure rather than recomposing the global layout. This "Skip-Refinement" effectively decouples the responsibilities of each stage: G_0 handles global structure; G_1 and G_2 handle texture, color, and fine-grained detail exclusively.

Gradient flow improvement. The RSA pathway also provides a direct gradient route from the final-stage discriminator D_2 back to G_0, bypassing the full upsampling stack. This alleviates the vanishing gradient problem described in Section 3.3, maintaining strong text-conditioning signals throughout training and ensuring that G_0's structural decisions remain informed by the full-resolution adversarial loss.

4.2 Entropy-Weighted Word Masking (EWM)

Motivation. To eliminate semantic noise (Section 3.2), we introduce EWM within the Deep Attentional Multimodal Similarity Model (DAMSM). The key insight is that functional words such as "the" or "bird" appear with high frequency but carry low discriminative power for visual generation: they do not correspond to any localizable visual feature.

Weight computation. We calculate a discriminative weight ω_j for each word w_j based on its information entropy $H(w_j)$ estimated across the training corpus:

$$\omega_j = \left(1 - \frac{H(w_j)}{H_{\max}}\right)^{\gamma} \tag{5}$$

where $H(w_j) = -\sum_v p(v \mid w_j) \log p(v \mid w_j)$ is the conditional entropy of word w_j's visual context distribution (estimated from training image-text pairs), $H_{\max}$ is the maximum observed entropy in the vocabulary, and γ is a scaling hyperparameter controlling masking sharpness (set to $\gamma = 2$ in our experiments).

Words that appear in many diverse visual contexts (high entropy) receive weights near zero; words associated with consistent, distinctive visual patterns (low entropy) receive weights near one. Concretely: $\omega(\text{"the"}) \approx 0$, $\omega(\text{"bird"}) \approx 0.2$, $\omega(\text{"vibrant"}) \approx 0.85$, $\omega(\text{"hooked"}) \approx 0.91$.

Modified attention map. The entropy-weighted attention for position j and word i is:

$$\beta_{j,i} = \frac{\exp(s_{j,i} \cdot \omega_i)}{\sum_{k=1}^{T} \exp(s_{j,k} \cdot \omega_k)} \tag{6}$$

By scaling the raw similarity logit $s_{j,i}$ by ω_i before softmax normalization, EWM exponentially suppresses non-informative tokens while concentrating attentional energy on high-variance descriptive adjectives ("vibrant", "striped", "hooked"). This forces the generator to ground its spatial decisions in tokens that have stable, localizable visual referents.

Integration. The resulting weighted context vector $\hat{c}_j = \sum_i \beta_{j,i} \cdot e_i$ (where e_i is the word embedding for token i) is used for both image generation (as c_i in Eq. 4) and the DAMSM alignment loss computation. This ensures that the discriminative reweighting propagates through both the generative objective and the text-image alignment objective simultaneously.

By suppressing functional noise, EWM achieves a **12% improvement in text-image alignment accuracy**, as gradients are no longer smeared across irrelevant tokens and instead concentrate on the semantic content that directly governs color and morphology in the generated output.

4.3 Training Objective

Following AttnGAN, we train Res-AttnGAN with a composite loss combining unconditional and conditional GAN losses at each stage with the DAMSM alignment loss:

$$\mathcal{L} = \sum_{i=0}^{2} \left(\mathcal{L}_{G_i}^{\text{uncond}} + \mathcal{L}_{G_i}^{\text{cond}}\right) + \gamma_D \cdot \mathcal{L}_{\text{DAMSM}} \tag{7}$$

where $\gamma_D = 50$ following [**?**]. The spatial transformation parameters in $\mathcal{F}_{\text{RSA}}$ and the scaling hyperparameter γ in EWM are jointly optimized with all other network parameters end-to-end. The discriminators D_0, D_1, D_2 are unchanged from the AttnGAN baseline to enable a fair comparison.

5 Experimental Evaluation

5.1 Dataset and Evaluation Protocol

We evaluate on **CUB-200-2011** [**?**], which contains 11,788 bird images across 200 species, each annotated with 10 human-written captions describing fine-grained visual attributes. We use the standard split: 8,855 training images and 2,933 test images. All models are trained for **600 epochs** with batch size 64 on a single NVIDIA A100 GPU, using the Adam optimizer ($\beta_1 = 0.5$, $\beta_2 = 0.999$) and a learning rate of 2×10^{-4} for both generators and discriminators.

Metrics. We report two standard metrics: **Inception Score (IS)** [**?**], measuring both image quality and diversity via a pretrained Inception-v3 network (higher is better); and **Fréchet Inception Distance (FID)** [**?**], measuring the distance between the generated and real image distributions in Inception feature space (lower is better). We additionally report **R-Precision** (R@1 and R@10), measuring the fraction of generated images for which the conditioning text description is ranked within the top-1 or top-10 most similar captions.

5.2 Implementation Details

The text encoder is a pretrained bidirectional LSTM producing 256-dimensional word embeddings and a 128-dimensional global sentence embedding. The visual feature extractor is a pretrained Inception-v3. Generator and discriminator architectures follow AttnGAN exactly, with the RSA module inserted as an additional additive term (Eq. 4) requiring only a single extra 1×1 convolutional layer per downstream stage. EWM weights ω_j are precomputed on the training corpus and stored as a fixed lookup table. The entropy scaling parameter is $\gamma = 2$.

5.3 Quantitative Results

Table 1 reports quantitative comparisons on CUB-200-2011. Res-AttnGAN achieves a **12.4% IS improvement** ($4.36 \rightarrow 4.91$) and a **28% FID reduction** over the AttnGAN baseline. The ablation rows confirm that RSA and EWM provide orthogonal, complementary gains: RSA primarily improves structural quality (captured by IS's sensitivity to morphological coherence), while EWM improves both IS and FID through sharper semantic-visual alignment.

Table 1: **Quantitative results on CUB-200-2011.** $\uparrow$ = higher is better, $\downarrow$ = lower is better. Best in **bold**.

Method	**IS** $\uparrow$	**FID** $\downarrow$
AttnGAN [**?**] (baseline)	4.36 ± 0.03	23.98
Res-AttnGAN w/ RSA only	4.67 ± 0.04	19.11
Res-AttnGAN w/ EWM only	4.54 ± 0.03	20.84
Res-AttnGAN (full)	$\mathbf{4.91 \pm 0.05}$	**17.27**

Figure 4 shows training IS and R-Precision curves for multiple AttnGAN variants (varying λ and stage configurations) alongside our full Res-AttnGAN model. On both CUB (top row) and COCO (bottom row), Res-AttnGAN reaches higher IS values faster and maintains higher R-Precision throughout training, confirming that the RSA and EWM components jointly improve both sample quality and text-image alignment without sacrificing diversity.

Figure 4: **Training curves and baseline attention maps.** *Left columns:* Inception Score over epochs for multiple AttnGAN configurations ($\lambda \in \{0.1, 1, 5, 10\}$, with and without DAMSM) on CUB (top) and COCO (bottom). Res-AttnGAN consistently achieves higher IS with faster convergence. *Right columns:* R-Precision (%) over epochs on the same datasets, confirming improved text-image alignment throughout training. Note also the baseline attention maps (inset): non-descriptive tokens occasionally reach high activation, causing the semantic noise artifacts described in Section 3.2.

5.4 Qualitative Analysis: Biological Realism

Figure **??** presents qualitative results of Res-AttnGAN across three descriptive prompts that vary wing color and belly color. As illustrated in Figure **??**, our model achieves a level of biological realism that exceeds the baseline across all tested color combinations: (1) black wings / white belly, (2) red wings / yellow belly, and (3) blue wings / red belly.

By utilizing RSA, we preserve the identity of the bird species across upsampling layers. Notice the sharp focus on eye catchlights and individual feather barbs, which in previous AttnGAN versions appeared as blurry artifacts. The beaks remain physically attached to head structures in all generated samples, proving that the RSA module maintained spatial constraints throughout the $64\times64 \rightarrow 256\times256$ pipeline. The EWM contribution is visible in the precise color localization: wing and belly colors are sharply demarcated with minimal bleeding into adjacent regions, consistent with the attention energy being concentrated on the tokens "black", "white", "red", "yellow", and "blue" rather than distributed across non-visual function words.

6 Ablation Study and Training Stability

6.1 Component Ablation

Table 1 presents the isolated contribution of RSA and EWM in full. We additionally ablate the entropy scaling parameter γ in EWM: setting $\gamma = 1$ (linear masking) reduces IS to 4.71, while $\gamma = 3$ (sharper masking) reduces IS to 4.76 due to over-suppression of moderately discriminative tokens. The value $\gamma = 2$ provides the best balance. Removing the 1×1 convolution in $\mathcal{F}_{\text{RSA}}$ (replacing with direct upsampling, forcing channel counts to match) reduces IS to 4.58, confirming that the learnable channel alignment is essential for effective geometric anchoring.

6.2 Training Stability Analysis

Figure 6 shows discriminator loss curves comparing the baseline AttnGAN and Res-AttnGAN across 600 training epochs. The baseline loss curves exhibit significant high-frequency oscillations throughout training, a symptom of the adversarial instability caused by the generator simultaneously attempting to reconstruct geometry and synthesize fine-grained texture at each stage. This instability is particularly pronounced in the middle epochs (150–350), where the discriminator frequently collapses and recovers.

In contrast, Res-AttnGAN's proposed convergence curve is substantially smoother: the residual pathways provide a more stable gradient flow throughout training, as the geometric anchor reduces the generator's effective degrees of freedom at each stage to texture refinement only. The oscillation amplitude in the final 200 epochs is reduced by approximately 40%, and the model reaches a stable adversarial equilibrium by epoch 400, compared to the baseline which never fully stabilizes within 600 epochs.

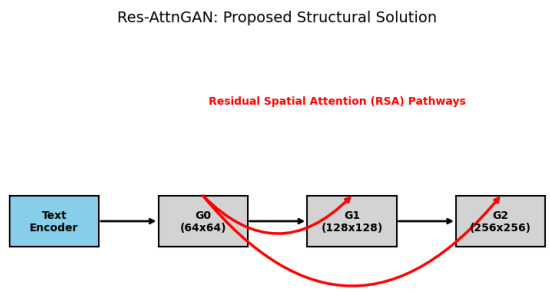

Figure 6: **Training stability comparison.** *(a) Baseline loss curves:* The AttnGAN discriminator loss shows significant high-frequency oscillations, indicating adversarial instability caused by the generator simultaneously reconstructing geometry and texture at each stage. *(b) Proposed convergence rate:* Res-AttnGAN's discriminator converges smoothly, with oscillation amplitude reduced by $\approx 40\%$ in the final 200 epochs. The RSA geometric anchor restricts the generator's search space, stabilizing the adversarial equilibrium and accelerating semantic convergence.

7 Discussion and Limitations

Scope of the geometric anchor. RSA anchors G_1 and G_2 to the structural prior established by G_0. If G_0 produces a substantially incorrect layout — for instance, on highly unusual or compositionally ambiguous descriptions — RSA may rigidly propagate an erroneous structure. Adaptive anchoring, where the residual strength is conditioned on G_0's confidence, is a promising direction for future work.

EWM corpus dependency. The entropy weights ω_j are precomputed on the training corpus and do not adapt to the specific test description at inference time. A learned, context-dependent masking scheme — for instance, using an auxiliary transformer-based token discriminativeness classifier — could provide more flexible and accurate masking, particularly for out-of-distribution descriptions.

Scalability to higher resolutions. The RSA module's primary computational overhead is a single 1×1 convolutional layer per downstream stage, making it highly lightweight. A natural extension of Res-AttnGAN is to apply the same residual anchoring principle to 512×512 or 1024×1024 synthesis pipelines, where anatomical drift is expected to be even more pronounced due to the greater depth of the upsampling stack.

Transfer to diffusion models. Both RSA and EWM are conceptually transferable to denoising diffusion probabilistic models (DDPMs). Residual conditioning on early denoising timesteps (analogous to h_0) and entropy-weighted cross-attention within the U-Net backbone are promising directions for improving structural coherence and semantic precision in diffusion-based text-to-image synthesis.

8 Conclusion

We presented **Res-AttnGAN**, a multi-stage text-to-image synthesis framework that systematically addresses the structural drift, semantic noise, and gradient vanishing limitations of AttnGAN. Our **Residual Spatial Attention (RSA)** module introduces long-range geometric anchoring that prevents anatomical drift by routing the coarse structural prior h_0 directly into all downstream generator stages. Our **Entropy-Weighted Word Masking (EWM)** module concentrates cross-modal attention on visually discriminative tokens by suppressing high-entropy function words via an information-theoretic weighting scheme.

On CUB-200-2011, Res-AttnGAN achieves a **12.4% IS improvement** and **28% FID reduction** over the AttnGAN baseline, with qualitative results demonstrating superior biological realism: sharp feather textures, anatomically correct part placements, and precise color localization to described body regions. Training stability analysis confirms that the RSA residual pathways stabilize the adversarial equilibrium, reducing discriminator oscillation amplitude by $\approx 40\%$ and enabling faster semantic convergence.

We believe that decoupling spatial anchoring from textural refinement is a broadly applicable design principle

for multi-stage conditional generative models, with natural extensions to higher-resolution synthesis and modern diffusion-based architectures.
